9.1 ASSUMPTIONS AND DEFINITIONS

Sunny-day failures are levee breaches that are not flood or seismic related. Historical data were used to estimate the rate at which the levee breaches occurred during non-flood and non-seismic conditions. These failures typically occur between the end of the late snowmelt from the Sierras, in late May, and the beginning of the rainy season, in early October. Sunny-day failures are addressed separately from flood-induced failures to differentiate between winter and summer events. Aside from seismic events, factors that can cause Delta levee failures in the summer period are different than the factors that can cause winter failures.

Levee failures resulting from flood hazard are discussed in Section 7 of this report. Factors that influence water stage frequencies during winter include the following hydrologic conditions: historical storms, storm surges, snow melt, rainfall and runoff, tides, and their combined effects.

Water stage frequencies associated with the summer, are controlled by tides and remote oceanic storm surges. Therefore, frequencies of failure for the two seasons are different, kept separate, and compared against historical observations for each season.

9.2 HISTORICAL INFORMATION

To estimate the sunny-day annual frequency of failures, the consulting team used the historical record of summer-time levee failures in the Delta since 1950. In this period, eight levee failures were recorded during summers that resulted in island flooding. Data prior to 1950 were not used because the information needed, such as water level, crest elevation, and failure mode, is either nonexistent, sparse, or lacks the necessary details to fully document failure conditions. Furthermore, levees prior to 1950 were much smaller than today’s levees.

Table 9-1 summarizes the information collected about sunny-day island flooding. Water levels in the nearby sloughs were obtained from gauge station historical records operated and maintained by the California Data Exchange Center (CDEC). Levee crest elevations were obtained from the Interferometric Synthetic Aperture Radar (IFSAR) data in the Geographic Information System files that the California Department of Water Resources (DWR) provided. Post-failure investigation reports are not available to provide detailed descriptions of the causes of the levee failures. The information provided in the column titled “Conditions at Time of Failure or Assumed Failure Mode” of Table 9-1 is anecdotal and relies on limited available data and communication with DWR personnel and the reclamation districts’ engineers.

Figure 9-1 shows the levee crest elevations versus the water stage (North American Vertical Datum of 1988 [NAVD88]) for seven of the eight levee breaches at the time of failure. Figure 9-2 shows the approximate locations of the breaches. A close examination of the data indicates that failures occurred during “unusual” high-tide conditions. An unusual high tide could be caused by offshore storm surges arriving in the Delta, planetary conditions resulting in higher gravitational pull from the concurrent alignment of the sun and the moon, or a combination of the two.

At Simmons-Wheeler in July 2005, the water rose above the crest of the levee at Suisun Marsh and overtopping may have caused the levees to fail. However, other eyewitness reports indicate also that the levee failure at Simmons-Wheeler may have been caused by rapid drawdown during a period of receding water levels.
Post-failure reports indicate that excavation activities at the landside toes of the levee may have caused the failure of Brannan Andrus Island in June 1972. At MacDonald Island in August 1982, the levee may have been breached as a result of dredging on the waterside toe of the levee. However, that information has not been confirmed in any written report. Generally, these failure events may be the result of a combination of high tide and pre-existing internal levee and foundation weaknesses caused by burrowing animals, internal compounded erosion of the levee and foundation through time, and human interventions such as dredging or excavation at the toe of the levee.

Burrowing animal activities and pre-existing weaknesses in the levees and foundation are the key weak links leading to levee failures. This is the case whether or not the failures occur during a high-tide condition. Most practicing engineers, scientists, and maintenance personnel in the Delta and Suisun Marsh believe that rodents are prolific in the Delta and use levees for burrowing. As a result, they cause undue weaknesses by creating a maze of internal and interconnected galleries of tunnels.

Underseepage and through-levee seepage are slow processes that tend to work through time by removing fines from levee and foundation material during episodes of high river levels. Cumulative deterioration through the years can lead to foundations ultimately failing by means of uncontrollable internal erosion that leads to slumping and cracking of levees.

Sunny-day levee failures all occurred during higher-than-typical daily high tides. The typical daily high tides over a 24-hour cycle in summer conditions are generally around elevation +5 feet (NAVD88) in the central-west Delta, and about +5.6 feet in Suisun Marsh (DWR 1995b). Water elevations at the times of the summer levee failures, as shown in Figure 9-1, were generally around elevation +6 feet (NAVD88) or higher.

9.3 ESTIMATION OF FREQUENCY OF SUNNY-DAY FAILURES

The frequency of historical sunny-day failures of levees in the Delta and Suisun Marsh was determined from the records of six such failures recorded in the Delta and two sunny-day failures in Suisun Marsh. Assuming 911 miles of Delta levees within the Mean Higher High Water (MHHW) boundary, a failure rate of $1.06 \times 10^{-4}$ /year/levee-mile or 0.0969 failure/year was estimated using the least square linear fit to the six data points for the Delta shown in Figure 9-3. The standard deviation around the linear trend line is 0.47.

Assuming 75 miles of Suisun Marsh exterior levees within the MHHW boundary, a failure rate of $4.76 \times 10^{-4}$ /year/levee-mile or 0.036 failure/year was estimated. The data points for the Suisun Marsh are too few to conduct a statistical regression analysis (trend line and standard deviation). The trend for Suisun Marsh is estimated to be an average of two failures over 55 years, and the standard deviation is assumed to be the same as for the Delta, short of any other information.

Because of having incomplete information on the exact causes of the sunny-day levee failures at each location and, therefore, the DRMS project team was unable to map out the various conditions leading to sunny-day failures by specific area in the Delta and Suisun Marsh. The project team assumed that the recurrence models of sunny-day failures have uniform probabilities throughout the Delta and Suisun Marsh, respectively. These two failure rates will be
applied to all levees in the two areas within the MHHW boundary, assuming the uniform probabilities shown in the preceding two paragraphs.
